Connecting, synchronising, and dating with tephras: principles and applications of tephrochronology in Quaternary research

David J. Lowe
School of Science, Faculty of Science and Engineering, University of Waikato, Hamilton, New Zealand 3240 (e-mail: d.lowe@waikato.ac.nz)

1. Introduction: what is tephrochronology?

Tephrochronology is a unique method for linking and dating geological, palaeoecological, palaeoclimatic, or archaeological sequences or events. The method relies firstly on stratigraphy and the law of superposition, which apply in any study that connects or correlates deposits from one place to another. Secondly, it relies on characterising and hence identifying or ‘fingerprinting’ tephra layers using either physical properties evident in the field or those obtained from laboratory analysis, including mineralogical examination by optical microscopy or geochemical analysis of glass shards or crystals (e.g., Fe-Ti oxides, ferromagnesian minerals) using the electron microprobe and other tools. Thirdly, the method is enhanced when a numerical age is obtained for a tephra layer by (1) radiometric methods such as radiocarbon, fission-track, U-series, (U-Th)/He, or Ar/Ar dating, (2) incremental dating methods including dendrochronology or varved sediments or layering in ice cores, or (3) age-equivalent methods such as palaeomagnetism or correlation with marine oxygen isotope stages or palynostratigraphy. Once known, that age can be transferred from one site to the next using stratigraphic methods and by matching compositional characteristics, i.e., comparing ‘fingerprints’ from each layer. Used this way, tephrochronology is an age-equivalent dating method.

Even if a tephra layer is undated, or if it is dated imprecisely, it nevertheless provides an isochron or time-plane (sometimes referred to as a ‘time-parallel’ marker bed) that allows the sequence in which it is found to be correlated with other sequences where it occurs. Herein lies the unique power of tephrochronology: deposits and their associated palaeoarchival evidence are thus able to be connected and synchronized — positioned precisely on a common time scale — using the tephra layer as a stratigraphically fixed tie-point, even where the tephra is poorly or undated. In this situation, the age scale is best envisaged as a length of elastic that can be stretched or contracted when numerical ages are obtained, or age precision is improved, whilst the tephra’s stratigraphic juxtaposition with respect to the enclosing deposits and associated archival data remains fixed on the ‘elastic’. When the tephra age is known, however, that age can be applied directly to the sequence where the tephra has been newly identified. This is because tephra layers are erupted over very short time periods (volcanic eruptions typically last for only hours or days to perhaps weeks or a few months or so at most), and thus each represent an instant in time, geologically speaking (Lowe, 2011).

A tephra layer from a powerful eruption can be spread widely over land, sea and ice, hence forming a thin blanket that has exactly the same age wherever it occurs (unless it has been reworked). For example, the Icelandic Fugloyarbanki tephra, identified in the NGRIP ice core from Greenland, has been dated at 26,740 ± 390 (1σ) calendar (cal.) years before AD 2000 on the basis of multi-parameter counting of annual layers in NGRIP (Davies et al., 2008). It forms a widespread marker horizon or isochron in marine deposits in the North Atlantic and on the distant Faroe Islands between Iceland and Scotland. Thus palaeoarchives at these widely separated localities are now able to be connected precisely. Moreover, the extent of the radiocarbon marine reservoir effect in this region at the time can be examined using the Fugloyarbanki tephra as an independent time-plane.

Article citation:
In the New Zealand region, the Kawakawa (or Oruanui) tephra, erupted from Taupo caldera c. 25,400 cal. yr BP (Vandergoes et al., 2013), similarly forms an extensive isochron linking numerous terrestrial and marine sequences to the same point in time (Pillans et al., 1993; Carter et al., 1995; Newnham et al., 2007a, 2007b; Holt et al., 2010; Alloway et al., 2013; Van Eaton and Wilson, 2013; Van Eaton et al., 2013) (Fig. 1).

Fig. 1. Isopachs of Kawakawa/Oruanui tephra (in centimetres) showing the tephra’s distribution extending >1000 km away from its source at Taupo caldera. Isopachs to the 10 cm mark are from Wilson (2001); beyond 10 cm, the thinner isopachs are based on relatively few sites and are indicative only (from Vandergoes et al., 2013). Trace occurrence in Northland is after Newnham et al. (2004).

Much of this article is based on Lowe (2011). A short article on tephrochronology is given by Lowe et al. (2015a), and Lowe et al. (2008a) partly updates Froggatt and Lowe (1990). Other reviews include those of Shane (2000), Alloway et al. (2013), Lowe and Alloway (2015), and Ponomareva et al. (2016). Numerous volcanological aspects of tephra studies are covered in detail by Sigurdsson (2015), and Smith et al. (2006) provided an introduction to New Zealand volcanology. Many historical aspects of tephra studies in New Zealand were described by Lowe (1990, 2014) and Lowe et al. (2008b). Special volumes containing tephra articles include those of Lowe et al. (2011a), Austin et al. (2014), and Saito et al. (2016). Articles that include, or focus on, archaeological applications beyond New Zealand include those of Riede and Thastrup (2012), Lane et al. (2014), Davies (2015), and Lowe and Alloway (2015).
2. More on nomenclature

Tephras (from the Greek *tephra* meaning ‘ashes’) are the explosively-erupted, unconsolidated pyroclastic (literally ‘fiery fragmental’) products of volcanic eruptions. They encompass all grain sizes: ash (grains <2 mm in diameter), lapillus or lapilli (64–2 mm), or blocks or bombs (>64 mm). Ash can be classed as coarse (2 mm–62.5 µm) and fine (<62.5 µm); lapilli can be divided into five classes from extremely fine to coarse (Cas et al., 2008). Further clast-size related information was reported by Fisher et al. (2006) and White and Houghton (2006). As noted above, tephrochronology in its original sense (*sensu stricto*) is the use of tephra layers as isochrons to connect, correlate, and synchronize sequences and to transfer relative or numerical ages to such sequences where the tephras have been dated (Fig. 2). It is not simply ‘dating tephras’. Rather, tephrochronometry is the term used to describe the dating of tephra layers either directly or indirectly. In recent times, the term tephrochronology (*sensu lato*) has been used broadly to describe all aspects of tephra studies as used, for example, by Alloway et al. (2013) (Table 1).

The terms ‘tephra’ and ‘tephrochronology’ were coined by Icelandic geoscientist Sigurdur Thorarinsson in his doctoral thesis “Tephrochronological studies in Iceland (University of Stockholm)” in 1944 (Thorarinsson, 1974, 1981; Lowe, 1990; Steinthorsson, 2012; Wastegård and Boygle, 2012; Davies, 2015). Often regarded as the ‘father of tephrochronology’, Thorarinsson was born a little over 100 years ago on 8 January 1912 and died 8 February 1983 (Lowe et al., 2011b). A special issue of the journal *Jökull* was published in 2012 to commemorate the centenary of his birth (Benediktsson et al., 2012).

Fig. 2. Nomenclature of tephra and derivative terms and their relationships with one another and with other terms including the near-synonym pyroclastic material. ‘Tephra’, by definition unconsolidated or ‘loose’ pyroclastic material, is used in four different senses (white rectangles across centre). The terms listed beneath the blue rectangular boxes at the very bottom should be abandoned (from Lowe, 2008a). Cryptotephra may also comprise crystal concentrations (mineral grains) rather than, or in addition to, glass shard concentrations (Table 1; Lowe, 2011; Matsu’ura et al., 2011, 2012).
Undertaking tephrochronology always requires tephrostratigraphy to some degree (Lowe, 2011). Tephrostratigraphy is the study of sequences of tephras and associated deposits, their distribution and stratigraphic relationships (superpositions), and their relative and numerical ages. It involves defining, describing, characterizing, and dating tephra layers using their physical, mineralogical or geochemical properties from field or laboratory-based observations, or both. In the last two decades, there has been a revolutionary development focussed on detecting diminutive, distal tephras that are invisible in the field and referred to as cryptotephras (Davies, 2015). From the Greek word kryptein, meaning ‘to hide’, cryptotephras usually comprise fine-ash-sized (typically <125 µm) glass shards or crystals, or both, preserved and ‘hidden’ in peats or in lake, marine or aeolian sediments or soils, or in ice cores (Table 1; Lowe and Hunt, 2001). Cryptotephrostratigraphy refers to the stratigraphic study of tephra-derived glass-shard, or crystal concentrations (e.g., Hogg and McCraw, 1983; Matsu’ura et al., 2011, 2012; Wastegård and Boygle, 2012; Lane et al., 2014), that are encompassed within sediments (including ice) or soils or paleosols but which are not visible in the field as layers. The term ‘cryptotephra’ has replaced the term ‘microtephra’ but the term ‘microshard’, defined as glass shards <32 µm in diameter, has been proposed by Lowe et al. (in revision).

Note that the letter ‘o’ rather than ‘a’ is the appropriate connecting letter in all these terms derived from tephra, and that the adjective ‘volcanic’ is redundant when referring to tephra. The term ‘airfall’ is no longer used (tephra-fall or tephra fallout, or ash-fall or ash fallout if appropriate, are used instead). Several other words in usage have tephra or tephros (‘ash coloured’) at their root but none normally is relevant to tephrochronological studies. ‘Tephrite’ refers to a typically ash coloured alkalic basaltic volcanic rock erupted effusively as lava, not explosively. ‘Tephroite’ is a mineral, Mn₃SiO₄, in the olivine group that is commonly ash-grey to olive or bluish green in colour. And ‘tephromancy’ is divination by means of sacrificial (human) ashes, requiring supernatural insight!

**Table 1.** Tephra-related nomenclature in brief (from Lowe, 2011, 2015).

*Note the spelling of ‘isochron’ (not ‘isochrone’), derived from Greek iso, ‘equal’, and Greek chronos, ‘time’. 

Lowe: QT Short Course 2016
3. Mapping tephras: from metre to sub-millimetre scale

Since the mid-late 1920s, tephras have been mapped using field and laboratory based methods in New Zealand. In the field, the most successful approaches have included the so-called ‘hand-over-hand’ method whereby relatively thick sequences of tephras (metre to decimetre scale) are traced from cutting to cutting (Fig. 3; Lowe, 1990) using their stratigraphy and salient physical properties including colour, bedding characteristics, or other features such as pumice density (e.g., hard vs soft) or colour, the presence of accretionary lapilli (e.g. Van Eaton and Wilson, 2013), or marker mineral grains (crystals) such as biotite visible via a hand lens. Distinctive marker beds provide a useful stratigraphic starting point in unravelling the complexities of a road cutting or other exposure (Fig. 4). The nature of buried soil horizons or loess associated with tephra layers may also provide helpful information in the field. Such methods are ultimately limited as the tephra layers thin away from source and lose diagnostic features in subaerial sequences, or where they become mixed together by soil-forming processes or by cryoturbation in periodically frozen landscapes.

But for several decades now, cores taken from lake sediments and peat bogs in Hawke’s Bay, Waikato, Taranaki, and Auckland have revealed a rich record of visible tephra layers a few centimetres to millimetres in thickness preserved at sites distant from source volcanoes (e.g., Lowe, 1988; Molloy et al., 2009; Augustinus et al., 2011; Lindsay et al., 2011; Turner et al., 2011; Green et al., 2014) (Fig. 5). Most recently, sub-millimetre-scale cryptotephra studies on such sediments have been initiated in the Waikato and Auckland regions (Table 2). Marine cores have also revealed detailed tephra records – which, together with those from lakes and bogs, provide a record of explosive volcanism that can be more comprehensive than that obtainable near to source because of burial or erosion of eruptives near volcanic centres (Fig. 6; Lowe, 2014). New developments in North America and elsewhere have been dramatic (Davies, 2015) and ‘ultra-distal’ cryptotephras have been described by Pyne-O’Donnell et al. (2012) (eastern USA, Lane et al. (2013) (eastern Africa), and Blockley et al. (2015) (Greenland), and, amazingly, include the identification of the Alaskan White River ash (~AD 860) in western/northern Europe (Jensen et al., 2014). Streeter and Dugmore (2013) advocated the development of high-resolution tephrochronology from studies in Iceland where they used digital photography to obtain thousands of stratigraphic measurements of multiple tephra layers intercalated with sediments at a resolution of ± 1 mm (see also Dugmore and Newton, 2012).

Fig. 3. Metre-thick, proximal, coarse, partly bedded pumiceous late Holocene rhyolitic tephra beds (mainly blocks/bombs and lapilli) and associated darker buried soil horizons (marking volcanic quiescence) evenly draping an antecedent strongly-rolling landscape near Taupo (from Lowe, 2011).
Fig. 4. Example of a stratigraphic marker bed in a road cutting, Hamilton. The prominent white bed mid-section is Rangitawa tephra (c. 340 ka). Lying at the base of strongly-weathered tephra beds and associated buried soils (Hamilton Ash sequence), rhyolitic Rangitawa tephra contains characteristic coarse-ash-sized golden platy crystals (biotite-kaolinite intergrade) and coarse-ash-sized quartz crystals. This widespread tephra, erupted near the end of MOI stage 10 (Holt et al., 2010; Alloway et al., 2013), overlies unconformably a dark reddish-brown buried soil >c. 0.78 Ma, about 1 m of volcanogenic alluvium, and (at the base) either the Ongatiti Ignimbrite (c. 1.23 Ma) (Lowe et al., 2001) or the Kidnappers Ignimbrite (c. 1 Ma) (Wilson et al., 1995). Photo: D.J. Lowe.

Fig. 5. Main tephra-producing Quaternary volcanic centres of North Island. The two most frequently active rhyolitic centres are Taupo and Okataina calderas (see Fig. 6). Egmont and Tongariro centres are andesitic, Tuhua (Mayor Island) is peralkaline, and the locally distributed tephras from Auckland Volcanic Field are basaltic. After Wilson and Leonard (2015).
Fig. 6. Interfingering stratigraphic relationships, ages, and volumes (as non-vesiculated, void-free magma, i.e., dense-rock equivalent, DRE) of tephras erupted from Okataina, Maroa, Taupo, and Mayor Island (Tuhua) caldera volcanoes in North Island, since ca. 55 ka cal. BP (from Lowe et al., 2015b, and based mainly on Jurado-Chichay and Walker, 2000; Shane et al., 2006; Wilson et al., 2009; Leonard et al., 2010; Danisik et al., 2012; Lowe et al., 2013; Vandergoes et al., 2013).
4. Fingerprinting

Tephra fingerprinting in New Zealand has been undertaken using a range of analytical methods, almost always in conjunction with stratigraphic and chronological criteria where available (Table 3). Accurate fingerprinting is an essential element (!) in developing any age models for tephras, and the level of probability that can be applied to their identification and correlation is an important consideration in quantitative tephrochronology. Ideally, multiple criteria (more than one thread of evidence) should be used to secure the correlation: for example, stratigraphic position together with mineralogical assemblage and glass major element composition. Numerical age data are also useful.

Table 2. Special techniques used to identify and map thin distal tephras, or detect cryptotephras in cores or sections, in New Zealand (after Lowe et al., 2008a) (see also Gehrels et al., 2008).

Mineralogy

One of the most common methods has been to use optical microscopy (using a petrological or polarizing microscope) to identify ferromagnesian mineralogical assemblages where such minerals are abundant. These minerals can be extracted using magnetic separators (e.g., Frantz) together with non-toxic heavy liquids (e.g., sodium polytungstate). With stratigraphic constraints, the relative abundances of ferromagnesian minerals typically allow a source volcano to be identified. For eruptives <30,000 cal. yr BP, orthopyroxene is always dominant in Taupo Volcanic Centre (TP)-derived tephras whereas biotite, hornblende, cummingtonite, or orthopyroxene predominate in Okataina Volcanic Centre (OK)-derived tephras (Table 4; Lowe et al., 2008a). Sometimes a mineral assemblage is sufficiently distinctive for an individual tephra – for example, Tuhua Tephra (from Mayor Island), which contains sodic phases such as aegirine – to be readily identified by only a few grains. However, the absence of diagnostic minerals does not necessarily negate an identification because minerals such as olivine are readily depleted by weathering, and biotite and orthopyroxene may be rapidly dissolved in some acid peat bogs (e.g., Hodder et al., 1991). Ferromagnesian minerals also tend to be sparse or absent at distal localities, having dropped out from proximal ash clouds earlier because of their high density. Recent studies of the OK-derived tephras (erupted since 30,000 cal. yr BP) have shown that all but two comprise multiple magma types (Table 4), adding complexity to the use of ferromagnesian minerals for correlation purposes but increasing in some the potential for fingerprinting by chemical analysis of constituent minerals and glass (see below). Andesitic eruptives are usually distinguishable from rhyolitic tephras because of their high pyroxene, or hornblende plus clinopyroxene, contents.

Microprobe analysis

In undertaking electron microprobe analysis (EMPA), sample preparation (Fig. 7) and probe operating conditions are critically important in deriving accurate and robust data, especially for glass which normally requires a defocussed beam to minimise volatilisation of Na and K (Froggatt 1992; Hunt and Hill, 1996, 2001; Turney et al., 2004; Lowe, 2011). However, Hayward (2012) and Hall and Hayward (2014) have developed robust protocols that enable the routine use of narrow beam diameters of 5 µm, and as low as 3 µm, without loss of Na. Such a development is extremely important because it enables many fine-grained samples to be analysed from wider, more distal geographic locations than previously, it reduces or prevents bias in data collection because most or all shards in a sample can be analysed, it enables more shards that are vesicular or microlite-rich (microlites are tiny mineral inclusions and can occur frequently in andesitic or basaltic glasses, and also in rhyolitic glasses) to be analysed than previously possible, and EPMA data acquisition is more easily automated and hence potentially more cost-effective (Hayward, 2012; Hall and Hayward, 2014; see also Pearce et al., 2014).

Appropriate standards must be checked (analysed) frequently and there is now a general requirement for analyses of such standards to be published alongside new EMPA data (e.g., Westgate et al., 2008). A revised set of protocols for microprobing glass (and reporting such analyses) was published by Kuehn et al. (2011) following an intensive interlaboratory comparison exercise in 2010-2011. Glass EMPA analyses are usually normalized (summed to 100%, most of the deficit being attributable to water) to enable valid comparisons of analyses. Some consider that such normalization can ‘cover up’ poor data (low totals), and should therefore not be undertaken (e.g., Pollard et al., 2006).

Analyses of Fe-Ti oxides, titanomagnetites and ilmenites, by EMPA have been useful for tephra fingerprinting (Table 4). An example of the use of minor elements (Mn, Mg) to distinguish five TP-derived tephras is given in Fig. 8. Egmont (EG) or Tongariro Volcanic Centre (TG) sources are usually determinable. The eruption temperature and oxygen fugacity (oxidation state of magma) of rhyolitic tephras – estimated using single-grain EMPA of Fe-Ti oxide pairs of titanomagnetite and ilmenite – have provided a relatively new way to distinguish and match tephras and, in some cases, magma batches within an eruptive sequence (Table 4).
Fig. 7. Preparation of crystals or glass shards in ‘blocks’ for analysis by electron microprobe. Grains must be polished flat before analysis (from Lowe, 2011).
The compositions of pyroxene, amphibole and olivine, obtained by EMPA, generally allow few individual tephra eruptive events to be identified but source volcanoes may be readily distinguished. For example, clinopyroxene and hornblende in EG-derived tephras are typically more calcic than those from TG, hornblende from these two andesitic sources is more pargasitic than that from the rhyolitic centres, and olivine in TG-derived tephras is forsteritic (Mg-rich) compared with that from Mayor Island which is fayalitic (Fe-rich). More recently, however, it has been demonstrated that the FeO and MgO contents of biotite derived from Kaharoa (two eruptive phases), Rotorua, Rerewhakaaitu, and Okarea tephras were different, thus enabling them to be distinguished from other OK-derived eruptives (Fig. 9).

The most commonly used tephra fingerprinting technique in New Zealand involves major-element analysis of volcanic glass shards using EMPA (Shane, 2000; Shane et al., 2006; Lowe et al., 2008a). Established initially in New Zealand in the early 1980s by Paul Froggatt (Froggatt and Gosson, 1982; Froggatt, 1983), EMPA of glass enabled volcanic sources to be readily identified for almost all eruptives <30,000 cal. yr BP in age. Although analyses of individual rhyolitic tephras of this age-range from Taupo or Okataina centres show many to be compositionally similar, some are distinguishable using bi-plots such as FeO or K₂O vs CaO content (Fig. 10), or using canonical discriminant function analysis (DFA) that incorporates eight or nine elements (oxides).

Detailed studies by EMPA, however, of thick sequences of proximal tephras erupted from Okataina have revealed much more compositional diversity and heterogeneity within individual lapilli-sized clasts and at different azimuths around the volcanic centre than previously recognised (Shane et al., 2008a). This heterogeneity is a consequence of the mingling of separate batches of magma that were tapped simultaneously or sequentially, accompanied by changes in wind direction, as eruptions proceeded. The recognition of more than one magma type in most of the OK-derived tephras has in some circumstances increased their potential for precise correlation in that some tephra beds might be identified uniquely, even where stratigraphic control is uncertain, because they were derived from two or three magma batches and so have multiple fingerprints or ‘handprints’ (Lowe et al., 2008a). For example, Kaharoa and Rotorua tephras are each the product of two magmas that can be distinguished on the basis of glass chemistry, one high (>4 wt%) and the other low (<4 wt%) in K₂O. Similarly, Rerewhakaaitu, Okarea, and Te Rere tephras are characterised by three magma types, the high K₂O-types (T2) containing distinctive biotite as well. However, it is also evident that the newly-recognised heterogeneity has increased complexity and potentially ambiguity, and glass compositions of some eruptive phases may overlap those for other tephras. An implication is that some tephras may have been misidentified (miscorrelated) in the past. The heterogeneity warns of the difficulty of characterising (thus fingerprinting) tephra beds using a limited set of distal samples from restricted dispersal sectors (Shane et al., 2008a).
Table 4. Ferromagnesian mineralogical assemblages and magma temperatures and oxygen fugacities of 22 marker tephras erupted since c. 30,000 cal. yr BP in New Zealand (from Lowe et al., 2008a)

Table 4 (contd)

aOpx, orthopyroxene (mainly hypersthene); Cpx, clinopyroxene (mainly augite); Hbe, hornblende; Cgt, cummingtonite; Bio, biotite; Aeg, aegirine; Aen, aenigmatite; Rie, riebeckite; Olv, olivine (fa, fayalite; fo, forsterite); Tuh, tuhualite.
bPre-eruption temperature data (mean ± 1 standard deviation).
cOxygen fugacity data reported in NNO units relative to the NiNiO buffer.
dT1–T3 represent separate magma types (early to late eruptive phases, respectively) identified by Smith et al. (2005) for some Okataina eruptive episodes.

**Fig. 9.** Biplot of FeO vs MgO (wt%) analyses for biotite obtained using EMPA from four OK-derived tephras showing that Okareka (magma type T2), Rerewhakaaitu (magma type T2), and Rotorua (magma type T2) are distinguishable from one another, and that Kaharoa Tephra comprises two populations relating to early (Kaharoa 1, magma type T1) and late (Kaharoa 2, magma type T2) phases of the eruption that correspond to high K<sub>2</sub>O and low K<sub>2</sub>O glass compositions, respectively (from Lowe et al., 2008a).

**Fig. 10.** Biplot of K<sub>2</sub>O vs CaO (wt%) analyses for glass obtained using EMPA from five TP-derived tephras illustrating that Taupo (Unit Y), Whakaipo (V) and Waimihia (S) generally are able to be distinguished from one another but Poronui (C), Opepe (E), and Taupo (Y) partly overlap (from Lowe et al., 2008a).
The correlation of andesitic tephras using glass chemistry generally has not been straightforward for various reasons including the multiplicity of units, the paucity of suitable glass for probing (few shards are free of microlite inclusions, and shards may be highly vesicular) and its vulnerability to weathering, and wide compositional ranges ($\text{SiO}_2 \approx 58-75 \text{ wt}\%$) and heterogeneity arising from multiple magma-mixing events (e.g., Shane et al., 2008b; Turner et al., 2008, 2011). Moreover, there are limited databases for tephras from EG and TG and hence direct correlation is uncertain without precise radiometric age or stratigraphic control (Shane, 2000; Lowe, 2011). However, analyses of glass from $>$40 EG-derived tephras by Shane (2005) showed them to be enriched in $\text{K}_2\text{O}$ ($>4 \text{ wt}\%$) and depleted in $\text{CaO}$, $\text{TiO}_2$ and $\text{FeO}$ in comparison with andesitic tephras erupted from TG, and hence easily distinguished (see also Donoghue et al., 2007; Lowe et al., 2008a). Further, the compositional variation (heterogeneity) in glasses from some individual andesitic tephras allows their identification within short stratigraphic intervals of c. 5,000–10,000 cal. years (Shane, 2005). Platz et al. (2007) proposed an evaluation procedure using mixing calculations to reduce microprobe-determined glass heterogeneity arising from plagioclase microlites, and this method is proving useful in cryptotepra studies (e.g., Gehrels et al., 2010). Most recently, Moebis et al. (2011) demonstrated that tephras from the three main centres of the Tongariro Volcanic Centre (Ruapehu; Ngauruhoe; Red Crater, Tongariro) could be distinguished by major elements, specifically via $\text{K}_2\text{O}$ and $\text{FeO}$ (Fig. 11).

Basaltic tephras in New Zealand, of restricted distribution, have been analysed by Shane and Smith (2000), Shane and Zawalna-Geer (2011), Needham et al. (2011), Shane et al. (2013), and Linnell et al. (2016) and others.

**Fig. 11.** Biplot of $\text{K}_2\text{O}$ and $\text{FeO}$ (total Fe expressed as $\text{FeO}$) derived by electron microprobe analyses of glass from tephras erupted from Ruapehu and Tongariro volcanoes younger than c. 12,000 cal. years, showing separation according to three sources (from Moebis et al., 2011, p. 359).
Trace- and rare-earth element (REE) data have not been widely employed in New Zealand tephrostratigraphy, although comprehensive studies have now been undertaken of Pleistocene tephras in the Auckland region (Pearce et al., 2008a) and in a core from ODP Site 1123 in the Pacific Ocean east of New Zealand (Allan et al., 2008). Earlier, various REEs and trace elements, based on analyses of small, bulk-glass samples, enabled some tephras from TP and OK within the <30,000 cal. yr BP time-frame to be distinguished. TP-derived tephras tend to show greater abundances of Sm, Eu, Tb, Lu, Hf, and Sc (Shane, 2000). Tuhua Tephra is distinguishable from both TP and OK-derived tephras because it has greater abundances of all REEs and other elements including U, Th, and Hf.

Because glasses from many OK-derived tephras are now known to be compositionally heterogeneous, the trace-element and REE analyses need to be re-examined and revised, probably using inductively coupled plasma mass spectrometry methods (LA-ICPMS). Advances in this method now enable it to obtain detailed major- and trace-element compositions from individual glass shards and for fingerprinting individual tephra beds or tephra successions of similar mineralogy or provenance, i.e., it is probably most useful to separate beds that are compositionally similar and not distinguishable using major element chemistry (Pearce et al., 1999, 2004, 2007, 2011, 2014; Allan et al., 2008; Westgate et al., 2008; Kuehn et al., 2009; Pearce, 2014; Tomlinson et al., 2015). The main advantage of a single-grain technique is that it allows mixed populations to be identified (such mixing arising from magmatic or volcanic eruption processes, or from post-depositional blending of thin tephras in soil-forming environments or the dissemination of glass shards in peat or in lake sediments, e.g., Gehrels et al., 2006).

Analyses by ion microprobe (secondary ionisation mass spectrometry, SIMS) of tephra components are also now being undertaken (e.g., Denton and Pearce, 2008) and look set to expand as the technique becomes more readily available (Lowe, 2011).

Somewhat unusually, diatom populations in the Kawakawa/Oruanui tephra and in the Okaia and Taupo tephras enable these deposits to be correlated. Morphometric analysis of *Aulacoseira* valve dimensions provides a helpful quantitative tool to distinguish environmental and eruptive processes within and between individual tephras (Van Eaton et al., 2013; Harper et al., 2015). The Kawakawa/Oruanui and Okaia diatom species and valve dimensions are highly consistent with a shared volcanic source, paleolake and eruption style (involving large-scale magma–water interaction). They are distinct from lacustrine sediments sourced elsewhere in the TVZ.

### 5. Statistical techniques to aid correlation

Statistical techniques in New Zealand have been limited mainly to DFA. Whilst not without potential flaws (see below), DFA has several advantages, the most important being that all or most elements in the analyses are taken into account non-subjectively, samples are able to be classified (matched) with known probability, and their degree of similarity is reflected in the Mahalanobis multidimensional distance statistic, $D^2$, which is preferable to the frequently used numerical ‘similarity coefficients’ measure. The efficacy of the technique can be tested using an iterative process to measure classification efficiency. DFA has been applied reasonably successfully to studies involving major-element analyses of glass (Fig. 12), Fe-Ti oxides or hornblende for both rhyolitic and andesitic tephras including composite (mixed) tephra deposits. In all these studies, many individual tephra layers or groups of tephras were able to be discriminated with a high-degree of probability (up to 100% classification efficiency) using either glass or titanomagnetite compositions, but some tephras, very similar compositionally, were less-well discriminated or unidentifiable using major elements alone.

The successful use of DFA is directly reliant upon the quality and comprehensiveness of the reference datasets against which unknowns are compared (e.g., Stokes et al., 1992; Cronin et al., 1996a, 1996b; Lowe, J.J. et al., 2007; Lowe, 2008a; Bourne et al., 2010). The generally poor analytical precision of some elements obtained by EMPA may limit the effectiveness of some DFA models, and the somewhat piecemeal glass compositional datasets for New Zealand tephras, acquired over several decades at a number of EMPA facilities, are of variable quality for several reasons, including changes in microprobe analytical procedures in the mid-1990s. Although further advances using DFA to identify and correlate rhyolitic tephras in New Zealand may now be feasible with the acquisition of the new glass major-element data (summarised in Smith et al., 2005; Lowe et al. 2008a), the approach must be
cautionary. Elsewhere, the statistical (or Euclidian) distance function (which is a variation of the similarity coefficient method), cluster analysis, or the Student’s t-test have been used (e.g., Pollard et al., 2006; Pearce et al., 2008b; Preece et al., 2011). Pouget et al. (2014) used principal component analysis to correlate tephras in California. New approaches have been developed by Bebbington and Cronin (2011), Turner et al. (2011), and Green et al. (2014). Statistical correlation methods were reviewed by Lowe et al. (in review). Ultimately such statistical techniques will rely on the development of more comprehensive, regional tephrostatigraphic and geochemical databases of uniformly high quality (Lowe, 2011).

Fig. 12. Example of use of DFA to compare degree of similarity of seven late Quaternary rhyolitic tephras in central North Island, New Zealand. Glass compositions of each tephra were combined using DFA into the first two canonical variates. The Mahalanobis distance between groups ($D_m^2$) is a direct measure of their multivariate similarity/dissimilarity based on all seven major oxides analysed, not just two or three (from Lowe, 2011, after Cronin et al., 1997).

6. Developments in dating methods and age modelling

Dating methods relevant to tephra studies have described by Lowe (2011) and Lowe and Alloway (2015) (Table 5). A key advance has been the development of the isothermal-plateau fission-track dating method (ITPFT) for glass (Alloway et al., 2013). It has enabled ages to be obtained on many distal tephras that previously were unable to be dated because their main component, glass, was unreliable because of annealing (e.g., Westgate et al., 2013). Examples of such applications are the dating of initial loess deposition in Alaska at about 3 million years ago (Westgate et al., 1990), dating Quaternary glacioeustatic sedimentary cycles in the Wanganui Basin (Pillans et al., 2005), and dating marine tephra sequences from ODP sites east of New Zealand, thus testing chronologies based on alternative methods (Carter et al., 2004; Alloway et al., 2005; Allan et al., 2008). Another promising method for more proximal deposits, until recently used mainly for pre-Quaternary petrological or provenance studies, is the use of U-Pb analyses to date zircons using SIMS techniques (e.g., SHRIMP: Brown and Fletcher, 1999; Wilson et
al., 2008; ID-TIMS: Crowley et al., 2007) or LA-ICPMS (e.g., Chang et al., 2006) (see also Dickinson et al., 2010). A new method involving U-Th-disequilibrium/U-Pb and (U-Th)/He zircon ‘double dating’ is being applied to tephra studies (e.g. Schmitt et al., 2010; Danisik et al., 2012, in press; Howe et al., 2014). The application of varved sediments to help derive tephra ages includes research reported by Zillén et al. (2002), Lane et al. (2015), and Ott et al. (2016).

For tephras erupted within the past c. 50,000–60,000 cal. years, the radiocarbon (14C) technique remains by far the most important method for developing age models (other methods are documented by Lowe et al., 2008a; Alloway et al., 2013; Westgate et al., 2013). Calendar dates on two late Holocene tephras, Kaharoa and Taupo, have been obtained by wiggle-matching log-derived tree-ring sequences dated by 14C. The date obtained for Kaharoa (1314 ± 12 AD) (95% probability) by Hogg et al. (2003) was supported by Bayesian statistical analysis of an independent 14C-age dataset (Buck et al., 2003). The main plinian phases of the Kaharoa eruption took place during the austral winter (on the basis of tree-ring data). The date for Taupo tephra is now established as 232 ± 10 AD (Hogg et al., 2012; 95% probability). This date contrasts with several other calendar dates suggested for this eruption and indicates that the Greenland ice-core date of 181 ± 2 AD, and the Roman and Chinese sunset date of c. 186 AD, are no longer viable. Tree-ring data and preserved plant macrofossils have shown that the Taupo eruption took place during the austral late summer–early autumn period, i.e. probably late March–early April.

Bayesian age modelling

Together with wiggle-matching methods, Bayesian age modelling, derived ultimately from the theorem of 18th Century Englishman, Thomas Bayes, is adding another revolutionary aspect to the construction of enhanced and more precise chronologies in tephrochronology (e.g., Blockley et al., 2007b, 2008, 2012; Lowe, J.J. et al., 2007; Lowe, 2011; Bronk Ramsey et al., 2015a, 2015b). For example, 14 Holocene and late Pleistocene tephras comprising a sequence from Waimihia Tephra to Rerewhakaaitu Tephra,
preserved in peat at montane Kaipo bog in eastern North Island, were dated by using flexible depositional age-modelling (similar to wiggle-matching) their stratigraphic order and 51 associated \(^{14}\)C-age points simultaneously against the IntCal04 calibration curve (Hajdas et al., 2006). The flexible depositional age-modelling of the Kaipo sequence was undertaken using the programme OxCal3, developed by Chris Bronk Ramsey, which utilises a Bayesian statistical framework (successor OxCal4: Bronk Ramsey, 2008, 2009). Subsequently, Lowe et al. (2008a) analysed the same age data independently using an alternative Bayesian age-depth modelling programme, Bpeat (Blaauw and Christen, 2005; Wolfarth et al., 2006; Blaauw et al., 2007).

The 2\(\sigma\)-age ranges for the tephras derived from both OxCal3 and Bpeat were listed in Lowe et al. (2008a), and are closely aligned. A revised age model for the Kaipo tephra sequence has been developed for the NZ-INTIMATE project using another Bayesian programme, Bacon (Blaauw and Christen, 2011), in conjunction with OxCal4 and the associated \(P_{\text{Sequence}}\) function (Bronk Ramsey, 2009) (Lowe et al., 2013). Older tephras (those erupted earlier than c. 18,000 cal. yr BP) were also re-dated using OxCal4 and the associated \(T_{\text{Boundary}}\) function (Lowe et al., 2013) (Fig. 13). The new age modelling has shown Waiohau tephra to have been erupted around 14,000 cal. yr BP (cf. c. 13,700 cal. yr BP in Lowe et al., 2008a). Regarding the very widespread Kawakawa/Oruanui tephra, its age has been problematic (Lowe et al. 2008a, 2010). Wilson et al. (1988) published a \(^{14}\)C age of c. 22,590 \(^{14}\)C yr BP, equivalent to about 27,000 cal. yr BP, but recent dating of optimal material using the \(T_{\text{Boundary}}\) function of OxCal4 showed this tephra is now dated firmly at 25,358 ± 162 cal yr BP (95% probability) (Vandergoes et al., 2013). In North America, Egan et al. (2015) refined the age of the eruption of Mazama tephra to 7682–7584 cal. yr BP (2\(\sigma\) range) using Bayesian modelling of a dataset comprising 81 \(^{14}\)C ages, consistent with, but more precise than, an age of 7627 ± 150 ice-core yr BP derived from GISP2.

**Fig. 13.** Bayesian-derived age models for nine Late Glacial to Holocene tephras. Ages derived from modelling for part of a peat sequence at Kaipo bog in eastern North Island using Bacon (from Lowe et al., 2013). Probability plots (all are equal in area) are coloured according to tephra source volcanoes: red, Okataina; orange, Taupo; green, Egmont/Taranaki; blue, Tongariro. Grey plots show the Bacon-derived start and end ages of the Late Glacial cool episode (i.e., New Zealand climate event NZce-3 of Barrell et al., 2013) between the Waiohau and Konini tephras.
7. Tephrochronology as a high-precision synchronization or correlation tool

A critical recent development has been the enhanced use of tephrochronology to affect more precise correlations between marine, ice-core, and terrestrial records. This application holds the key to testing the reliability of high-precision correlations between sequences and current theories about the degree of synchrony of climate change at regional to global scales – provided the tephra correlation is certain (e.g., see Denton and Pearce, 2008). Numerous studies have utilised this unique chronostratigraphic capability (e.g. Fig. 14; Lowe, 2008a; Zanchetta et al., 2011; Davies, 2015).

In Europe, Blockley et al. (2007a) for example showed that there is now potential to independently test climate synchrony between Greenland and Europe as far south as the Alps via the Vedde ash. Similarly, Rasmussen et al. (2008) correlated the NGRIP, GRIP, and GISP2 ice core records across marine oxygen isotope stage 2 using mainly tephras as a means of applying the recent NGRIP-based Greenland ice-core chronology to the GRIP and GISP2 ice cores, thus facilitating the synchronizing of palaeoclimate profiles of the cores in detail. Remarkably, Lane et al. (2011, 2012) have now linked northern, central, and southern European climate records in part using cryptotephrochronology. The RESET project (RESponse of humans to abrupt Environmental Transitions) has also led to major advances in European tephra and cryptotephra studies including the development of a so-called ‘tephra lattice’ (Lowe et al., 2015c) whereby new tephrostratigraphical data generated by the project augment previously-established tephra frameworks for the region, and underpin a more evolved tephra ‘lattice’ that links palaeo-records between Greenland, the European mainland, sub-marine sequences in the Mediterranean, and North Africa. A tephra database has also been constructed (Bronk Ramsey et al., 2015).

The Australasian INTIMATE project, built along similar lines to the very successful INTIMATE project (integration of ice-core, marine and terrestrial records) of the North Atlantic and Greenland (Lowe, J.J. et al., 2008; Davies et al., 2012, 2014; Blockley et al., 2014; Bourne et al., 2015), has developed a climate event stratigraphy for the region for the past 30,000 years (Alloway et al., 2007; Barrell et al., 2013). The role of tephrochronology in linking all of the selected palaeoenvironmental records (apart from those based on speleothems) has been highlighted (Fig. 14; Lowe et al., 2008a, 2013). The advantage provided by key marker tephras in the NZ-INTIMATE project led to the development of new age models based on Bayesian probability methods noted above.

Tephras also provide the means to help quantify the marine reservoir effect for correcting the marine-based radiocarbon time-scale, as shown by studies in the Mediterranean Sea, the Adriatic Sea, the North Atlantic, and the South Pacific Ocean (e.g., Sikes et al., 2000; Lowe, J.J. et al., 2007; Carter et al., 2008; Lowe et al., 2013; Olsen et al., 2014). Further, they enable AMS-based radiocarbon dating of pollen concentrates or biological remains to be evaluated, and for demonstrating and hence correcting for the ‘hard water’ effect in dating lake sediments (Lowe, 2008a).

Tephrochronology, long used to provide ages on early hominins, is being increasingly applied to archaeology and studies of humans in antiquity (e.g., Tryon et al., 2008, 2009, 2010), including determining the timing and extent of initial human impacts on landscapes and ecosystems such as those of Great Britain, Ireland, Iceland, Scandinavia, and New Zealand (e.g., Dugmore et al., 2000, 2007; Lowe et al., 2000; Hogg et al., 2003; Wastegård et al., 2003; Edwards et al., 2004; Lowe and Newnham, 2004; Lowe, 2008b; Streeter et al., 2012; Riede and Thastrup, 2013). The potential key role of cryptotephrochronology in underpinning the study of the adaptation of humans to climatic change in Europe since about 20,000 years ago was highlighted by Blockley et al. (2006), and most recently further findings from the RESET project were published in a remarkable paper by Lowe et al. (2012). Noteworthy tephrochronological studies with a disease, medical, and forensic focus have also been undertaken recently (e.g., Newnham et al., 2010; D’Costa et al., 2011; Streeter et al., 2012; Lavigne et al., 2013). A new method developed at the universities of Waikato and Adelaide to extract DNA preserved in allophane-rich buried soils (paleosols) on Holocene tephras near Mt Tarawera was published by Huang et al. (2016).
Fig. 14. Compilation of partial high-resolution palaeoenvironmental records spanning the interval c. 28,000 to 9500 cal. yr BP and showing how sites are linked by one or more tephra isochrons (NZ-INTIMATE project). Antarctic (EPICA Dome C) and Greenland (GISP2) records shown for comparison. The climatic events 1–5 are based on the speleothem record obtained from northwest South Island (NWSI) (Williams et al., 2005, 2010). (1) eLGM, ‘extended’ Last Glacial Maximum (Newnham et al., 2007a); (2) LGIT, last glacial–interglacial transition; (3) LGWP, late-glacial warm period; (4) LGR, late-glacial reversal; (5) EHW, early-Holocene warming. The boundary between events 1 and 2 is marked by Rerewhakaaitu Tephra (Newnham et al., 2003); the boundary between events 3 and 4 is marked approximately by Waiohau Tephra (Newnham and Lowe, 2000); the end of event 4 is marked by the closely spaced couplet of Konini and Okupata tephras, the former tephra essentially marking the start of the Holocene at c. 11,700 cal. yr BP in northern New Zealand (Walker et al., 2009). Evidence for event 4 (late-glacial reversal) (brown shading) is recorded at Kaipo, Otamangakau, MD97-2121 and to a lesser degree at Pukaki crater (see also Putnam et al., 2010, 2013; Newnham et al., 2012; Barrell et al., 2013; Sikes et al., 2013; Williams et al., 2015).

8. Summary and conclusions

Tephrochronology, the characterisation and use of volcanic-ash layers as a unique chronostratigraphic linking, synchronizing, and dating tool, has become a globally-practised discipline of immense practical value in a wide range of subjects including Quaternary stratigraphy, palaeoclimatology, palaeoecology, palaeolimnology, physical geography, geomorphology, volcanology, geochronology, archaeology, human evolution, anthropology, ancient DNA studies, and human disease and medicine. The advent of systematic studies of cryptotephras – the identification, correlation, and dating of sparse, fine-grained glass-shard concentrations ‘hidden’ within sediments or soils – over the past ~20 years has been revolutionary (Table 6). New cryptotephra techniques developed in northwestern Europe and Scandinavia in particular – and in North America most recently – adapted or improved to help solve problems as they arose, have now been applied to sedimentary sequences (including ice) on all the continents. The result has been the extension of tephra isochrons over wide areas hundreds to several thousands of kilometres from source volcanoes. Taphonomic and other issues, such as quantifying uncertainties in correlation, provide scope for future work (Lowe, 2011; Davies, 2015).

Developments in dating and analytical methods have led to important advances in the application of tephrochronology in recent times. In particular:

(i) the ITPFT (glass fission-track) method has enabled landscapes and sequences to be dated where previously no dates were obtainable or where dating was problematic;
(ii) new EMPA protocols enabling narrow-beam analyses (<5 μm) of glass shards, or small melt inclusions, have been developed, meaning that small (typically distal) glass shards or melt inclusions <~10 μm in diameter can now be analysed more efficaciously than previously (and with reduced risk of accidentally including microlites in the analysis as could occur with wide-beam analyses);
(iii) U-Th-disequilibrium/U-Pb and (U–Th)/He zircon dating permits dating of tephas as young as 2.5 ka and in the range beyond that for routine $^{14}$C dating and below the range for routine Ar/Ar dating (Danisik et al., in press);
(iv) LA-ICPMS method for trace element analysis of individual shards $\ll 10$ $\mu$m in diameter is generating more detailed ‘fingerprints’ for enhancing tephra-correlation efficacy (Pearce et al., 2011, 2014; Pearce, 2014; Tomlinson et al., 2015); and
(v) the revolutionary rise of Bayesian probability age modelling has helped to improve age frameworks for tephas of the late-glacial to Holocene period especially.

Developments in the understanding of magmatic heterogeneity at some volcanoes have shown that multiple fingerprints may arise according to tephra-dispersal direction during a ‘single’ eruption episode, adding complexity and the need for a careful approach in making long-range correlations. New debates on how various statistical methods should be used to aid correlation have emerged recently. The applications of tephrochronology and cryptotephochronology are now seen as key correlation or ‘synchronization’ tools in high-resolution palaeoclimatic projects such as INTIMATE (Integration of ice-core, marine and terrestrial records since 30,000 years ago) and in dating, integrating and interpreting human-environmental interactions in antiquity. New INQUA-based projects SHAPE (Southern Hemisphere assessment of palaeoenvironments) and CELL50K (Calibrating environmental leads and lags over the last 50 ka) will utilise tephrochronology and cryptotephochronology as well as other dating methods to meet their objectives.

INTAV, the leading INQUA-based global group of >120 tephrochronologists (Table 6), remarkably, now contains many geoscientists working in non-volcanic countries. These ‘neo-tephrochronologists’ have added new enthusiasm and skills to those of the geoscientists working on the typically thick, complex, multi-sourced tephrostratigraphic sequences in ‘traditional’ volcanic regions – Japan, New Zealand and western USA, for example – in an excellent example of intra-disciplinary mutualism (Froese et al., 2008; Lowe, 2008a; Lowe et al., 2015a). An INTAV-led project INTREPID (Enhancing tephrochronology as a global research tool through improved fingerprinting and correlation techniques and uncertainty modelling) was initiated in 2009 and will continue from 2013 to 2015 as INTREPID-II. Papers from the INTAV conference “Active Tephra” held in Kirishima, southern Japan, in 2010 were published by Quaternary International (Lowe et al., 2011a). An INTREPID-led Bayesian age-modelling course was held in San Miguel de Allende, Mexico, in August 2010. In May, 2011, a workshop on the Eyjafjallajökull eruptions of 2010, and their implications for tephrochronology, volcanology, and Quaternary studies, was held in Edinburgh, U.K., by the ‘Tephra in Quaternary Science’ (TIQS) group (e.g., see Stevenson et al., 2012). This meeting was also sponsored in part by the INTREPID project. A one-day tephra meeting on marine tephrochronology, held in October, 2011, London, has led to the publication of a volume entitled “Marine tephrochronology” (Austin et al., 2014). In August 2014, a meeting, ‘Tephra 2014: Maximizing the potential of tephra for multidisciplinary science’, was held in Portland, Oregon, USA, under the INTAV banner. Two symposia comprising more than 50 papers on tephra/cryptotephra studies and tephrochronological applications in palaeoenvironmental reconstructions, and in archaeology and studies of natural hazards, were held at the full INQUA Congress being in Nagoya, Japan, in late July-early August 2015. A number of the papers are being written up for a special issue of Quaternary Geochronology “Advancing tephrochronology as a global dating tool: applications in volcanology, archaeology, palaeoclimate and geohazard research” due out later this year.

In April 2016, a new overarchign project, EXTRAS, “EXTending TephRAS as a global geoscientific research tool stratigraphically, spatially, analytically, and temporally within the Quaternary”, was initiated by INTAV.
Table 6. Some recent advances in methodology and applications in global tephra studies (after Lowe, 2008a, 2011; see also Davies, 2015; Danisik et al., in press)

<table>
<thead>
<tr>
<th>Advance/method</th>
<th>Application</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Cryptotephra studies: identifying, correlating, and dating ash-sized glass-shard and/or crystal concentrations (not visible as layers) ‘hidden’ within sediments (including ice) or soil</td>
<td>Extending isochrons over wider areas, some &gt;7000 km from volcano source including ‘ultra-distal’ (hence see 4), and improving records of volcano eruption history and thus developing better models of volcanic hazards and their mitigation</td>
</tr>
<tr>
<td>2. (a) Isothermal-plateau fission-track dating of glass (ITPFT) and (b) U-Th-disequilibrium/U-Pb and (U–Th)/He zircon dating</td>
<td>(a) Dating tephras (especially those comprising only glass shards), hence dating landscapes or palaeoenvironmental or geoarchaeological sequences not previously datable at distal locations; (b) permits dating as young as 2.5 ka and in the range beyond $^{14}$C and below Ar/Ar</td>
</tr>
<tr>
<td>3. Laser-ablation inductively-coupled plasma mass spectrometry (LA-ICP-MS) and ion microprobe (SIMS) analysis of single grains</td>
<td>Correlation of tephras using trace elements and REEs of glass shards (especially of tephras with similar major-element compositions as determined by electron microprobe), with enhanced reliability obtained using single-grain analysis that can reveal magma mingling or contamination</td>
</tr>
<tr>
<td>4. Connecting and dating palaeoenvironmental sequences and geoarchaeological deposits with high precision using tephras or cryptotephras as isochrons</td>
<td>Classical tephrochronology applied in high-resolution palaeoclimatic projects such as INTIMATE to test synchronization of various stratigraphic records, correcting for marine reservoir or hard-water effects, and dating, integrating and interpreting human-environmental interactions in antiquity</td>
</tr>
<tr>
<td>5. Bayesian probability analysis of age sequences involving tephras</td>
<td>Bayesian methods are providing enhanced and more precise chronologies for tephrostratigraphic sequences via OxCal, BCal, Bpeat, Bacon (etc)</td>
</tr>
<tr>
<td>6. Recognition of heterogeneity in the composition of some tephras, especially high vs low K$_2$O contents; mainly by analysis of glass components but also of minerals (e.g., biotite)</td>
<td>Petrological insight into magma processes such as mingling and volcano eruptive histories, including the finding that multiple fingerprints of some tephras differ according to direction of dispersal</td>
</tr>
<tr>
<td>7. Improving the reliability of electron microprobe-derived analyses of fine-grained glass and melt inclusions (&lt;5 µm), and of microlite-rich andesitic glass through development of new narrow-beam protocols</td>
<td>New procedures to evaluate and correct for common microlite presence in andesitic glass shards, and the development of protocols for use of narrow beams in microprobe analysis, enable fine glass shards and melt inclusions (&lt;5 µm) to be analysed more efficaciously than before</td>
</tr>
<tr>
<td>8. ‘Neoformation’ of International Focus group on Tephrochronology and Volcanism (INTAV) in 2007 (previously known as SCOTAV and COT; see Lowe et al., 2011b) through to 2019 and beyond</td>
<td>INQUA*-based global group of tephra specialists with interests in developing and improving analytical techniques of known reliability to characterize tephras, to map their distributions and improve volcano eruptive histories, to develop high-precision age models for tephras, and to apply tephrochronology to numerous disciplines as a precise correlation and dating tool</td>
