

Ecology of endolithic lichens colonizing granite in continental Antarctica

Asunción DE LOS RÍOS, Jacek WIERZCHOS, Leopoldo G. SANCHO,
T. G. Allan GREEN and Carmen ASCASO

Abstract: In this study, the symbiont cells of several endolithic lichens colonizing granite in continental Antarctica and the relationships they have with the abiotic environment were analyzed *in situ*, in order to characterize the microecosystems integrating these lichens, from a microecological perspective. Mycobiont and photobiont cells, the majority classified as living by fluorescent vitality testing, were observed distributed through the fissures of the granite. The fact that extracellular polymeric substances were commonly observed close to these cells and the features of these compounds, suggest a certain protective role for these substances against the harsh environmental conditions. Different chemical, physical and biological relationships take place within the endolithic biofilms where the lichens are found, possibly affecting the survival and distribution of these organisms. The alteration of bedrock minerals and synthesis of biominerals in the proximity of these lichens give rise to different chemical microenvironments and suggest their participation in mineral nutrient cycling.

Key words: Antarctica, endoliths, EPS, lichens, microecology, mineral-lichen interactions

Introduction

The Antarctic continent is the coldest, driest, windiest and most isolated landmass on Earth, yet despite these harsh conditions, there is still substantial terrestrial vegetation (Robinson *et al.* 2003). As part of this vegetation, many lichen species are components of lithobiontic communities (Seppelt *et al.* 1995; Castello & Nimis 1997; Øvstedal & Lewis-Smith 2001). Some of these lichens can withstand extreme environmental conditions and live on the surface of rocks. However, others appear to avoid these conditions by colonizing the inside of lithic

substrata (Wierzechos & Ascaso 2001; Ascaso & Wierzechos 2003; De los Ríos *et al.* 2005). Thus, we can find microbial life in areas where the environmental conditions preclude the colonization of rock surfaces (Friedmann 1982; Green *et al.* 1999).

The study of lithobiontic microorganisms in general, and endolithic lichens in particular, has met with numerous difficulties. The symbionts of the latter are not only hidden in the hard lithic substratum but their most important interactions are those established with their immediate physical environment, i.e. the lithic substratum. Hence endolithic lichens require analyses on a microecological scale, for which the approaches normally used for ecological studies on epilithic lichens are inappropriate. The physical organization of lichen symbiont cells within local lithic microenvironments and interrelations between these and the surrounding environment must be analysed from a microecological perspective. Microscopy is an ideal technique for such studies, especially

when applied *in situ*, that is, when the biological components are not separated from the lithic material (Ascaso & Wierzbos 2003; De los Ríos *et al.* 2005). Using this technique, the zone of the lithic substratum colonized by lichens is seen as complex organic-mineral interfaces composed of a range of microorganisms, the organic compounds generated by them, together with inorganic materials. At these interfaces, lichenized algae and fungi, sometimes with free-living microorganisms, are organized as biofilms (De los Ríos *et al.* 2002). The suite of microorganisms comprising these biofilms and their biotopes where different inter-relationships are established, constitute a tiny ecosystem or microecosystem (De los Ríos *et al.* 2003). In the present study, we have used *in situ* microscopy techniques to characterize both the biological and abiotic components of microecosystems integrating endolithic lichens from two sites in continental Antarctica, and examined the interactions occurring in the system on a microecological scale. This work forms part of our ongoing project designed to characterize different ecological aspects of endolithic lichens in an effort to improve our understanding of how these lithic microecosystems function.

Materials and Methods

Materials

Fragments of granite rock were collected from several sites near Canada Glacier, Taylor Valley (Dry Valleys, 77°37'S 162°59'E) and Cape Geology, Granite Harbour (Ross Sea coast 77°00'S 162°00'E). Rock samples, 0.5–1 cm thick, with visible signs of endolithic microbial growth were placed in sterile polyethylene bags, transported by air to our laboratory and stored dry at –20°C until processing.

Transmission electron microscopy examination

Fragments of endolithic biofilm were removed from the rock under the stereomicroscope using a sterile needle and embedded in 2% (w/v) agar. Small pieces of agar containing the microbial cells were then immediately fixed in glutaraldehyde and osmium tetroxide solutions, dehydrated in a graded ethanol series, and embedded in Spurr's resin following the protocol described in De los Ríos & Ascaso (2001). Ultrathin

sections were post-stained with lead citrate (Reynolds 1963) and observed in a Zeiss EM910 transmission electron microscope (TEM).

Scanning Electron Microscopy

Low Temperature

Fragments of rock colonized by lichens were examined using Low Temperature Scanning Electron Microscopy (LTSEM). Small fragments were mounted using O.C.T. compound (Gurr) and mechanically fixed onto the specimen holder of the cryotransfer system (Oxford CT1500). These samples were plunge-frozen in subcooled liquid nitrogen and then transferred to the preparation unit. The frozen specimens were cryo-fractured and etched for 2 min at –90°C. After ice sublimation, the etched surfaces were gold sputter coated and the specimens then placed on the cold stage of the SEM chamber. Fractured surfaces were observed under a DSM960 Zeiss SEM microscope at –135°C under conditions of a 15 kV acceleration potential, 10 mm working distance and 5–10 nA probe current.

Back-Scattered Electron Mode and Energy Dispersive X-ray Spectroscopy

Fragments of granite colonized by endolithic lichens were processed for scanning electron microscopy with back-scattered electron imaging (SEM-BSE) and/or energy dispersive X-ray spectroscopy (EDS) analysis according to a method described by Wierzbos and Ascaso (1994). The fragments, after fixing and dehydration in an ethanol series, were embedded in LR-White resin. Transverse sections of polished surfaces of the rock were examined using a DSM 960 A Zeiss microscope.

Confocal Scanning Laser Microscopy

For Confocal Scanning Laser Microscopy (CSLM), the rock samples were prepared according to a procedure based on the glutaraldehyde-enhanced fluorescence method used for plant tissues (Wierzbos & Ascaso 2001). In brief, the samples were first fixed in glutaraldehyde, dehydrated in a graded series of ethanol solutions, and embedded in LR-White resin. Blocks of resin-embedded rock samples were cut transversely, finely polished and observed using an LSM 310 Zeiss confocal microscope.

Fluorescence labelling

Fluorescence assays were performed on fresh pieces of rock containing endolithic lichens. The LIVE/DEAD BacLight Kit L-13152 (Molecular Probes) was used to distinguish living and dead symbiont cells following the method described in Wierzbos *et al.* (2004). This kit contains two proprietary nucleic acid stains that differ in their ability to penetrate bacterial cell membranes. The green fluorescence nucleic acid stain, SYTO 9, labels all cells and the red fluorescence nucleic acid stain, propidium iodide, only penetrates cells with damaged

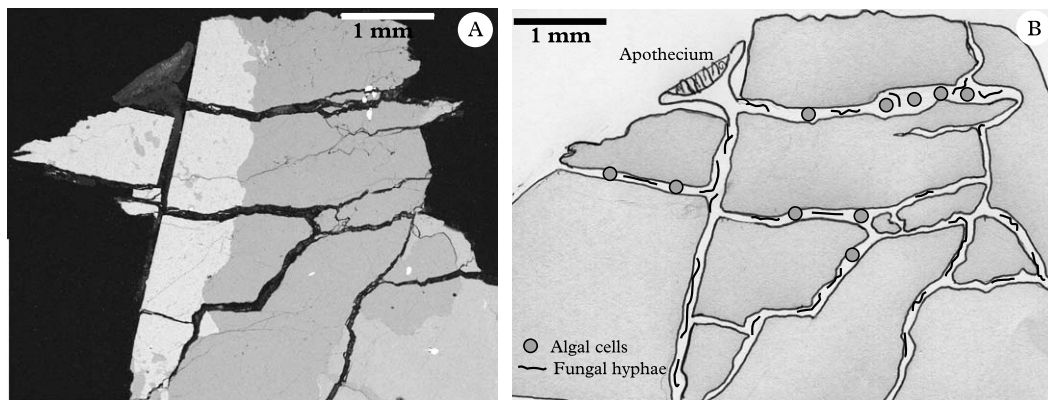

FIG. 1. Distribution of endolithic lichen symbiont cells and their structures through the fissures. A, SEM-BSE image of a rock colonized by *Lecidea* sp.; B, model diagram corresponding to the area in Fig. 1A.

membranes and quenches the green SYTO 9 stain. After fluorescence staining, the samples were processed for CSLM examination. They were fixed in paraformaldehyde, dehydrated in a graded ethanol series, and embedded in LR-White resin. The fluorescence intensity of living and dead microorganisms was then determined by CSLM double-channel scanning using an excitation wavelength of 488 nm. SYTO 9 (green fluorescent dye) fluorescence intensity was measured at emission wavelengths between 515–545 nm for the detection of living microorganisms, and fluorescence intensity generated by propidium iodide was measured at emission wavelengths longer than 570 nm to detect dead microorganisms. Each channel was displayed in a single colour (green and red respectively) and the images were superimposed using the Adobe Photoshop program. In the final image, cells with intact cell membranes were stained only green whereas cells with damaged membranes had red nuclei.

Results

Endolithic biota colonizing Antarctic granite

The endolithic microecosystems of Granite Harbour and the Dry Valleys materials examined contained many different microorganisms. In some samples, the symbionts of endolithic lichens constituted the predominant biota. These lichen-dominated endolithic zones coincided with the presence of epilithic lichens or areas where the fruiting bodies of endolithic lichens occurred (Fig. 1A). Figure 1B provides a diagram of how the algal and fungal cells are distributed

through the fissures of the granite. The association observed between fungal hyphae and algal cells (Fig. 2A), as well as the connection in several cases with identified external fruiting bodies allows the identification of lichen symbiont cells. Cyanobacteria were also observed but these occupied different zones within the rocks and were not observed close to the lichens. Heterotrophic bacteria were frequently observed in cyanobacterium-rich communities but were less common around endolithic lichen symbionts.

Most lichenized algal and fungal cells in these endolithic habitats appeared embedded in a polymeric matrix. Figure 2B shows an endolithic mycobiont cell with numerous vacuoles within a thick extracellular layer (arrows). Extracellular polymeric substances (EPS) were detected around the different microorganisms forming the biofilm. The image in Figure 2C, obtained by LTSEM, shows the polymeric nature of the extracellular compounds (arrows) associated with mycobiont cells at the interface between an epilithic lichen thallus and the lithic substratum. These EPS produced by epilithic lichens extended as far as the endolithic biofilms observed in nearby fissures (arrow in Fig. 2D).

Several colonized fissures in granite from both geographical areas were seen to be fully

FIG. 2. Lichen symbiont cells colonizing Antarctic granite. occupied by lichenized algal cells and fungal hyphae (Figs 2A & 3A). Figure 3A is a 3-D image obtained by CSLM showing the spatial arrangement of endoliths in different fissures of a rock sample from Canada Glacier. Mycobiont hyphae were present in all fissures occupied by the lichen (Fig. 3B), even very narrow fissures (Fig. 3C), but algal

cells were detected only in some sites and were more commonly observed in zones closest to the surface (Fig. 3D) than in the deeper rock areas (Fig. 3A).

The use of the *BacLight* Kit revealed living hyphae intermixed with dead or injured hyphal cells in several zones of the lithic substratum (Fig. 3E). In some zones,

95–100% of the cells were alive (green hyphae without red stained nuclei) but within some fissures of the substratum, we were also able to distinguish areas in which 20–30% of the fungal hyphae were dead (green hyphae with red nuclei in Fig. 3E). Both living and dead photobiont cells were also detected in an endolithic lichen inside the lithic substratum where the nuclei of only a few *Trebouxia* cells stained red (red arrows), indicating the damaged state of the cell membranes (Fig. 3F).

Mineral components of biofilms containing endolithic lichens

Mineral components mixed with the lichen cells were observed in the fissures and cavities within the rock substratum. Sometimes it was difficult to distinguish between the part of a fissure occupied by mycobiont hyphae and that filled with mineral fragments (Fig. 4A). Aluminosilicate minerals were found to be especially closely associated with hyphae (arrows in Fig. 4B). The element distribution map obtained by EDS analysis indicates that the minerals observed in the proximity of the hyphae were fairly heterogeneous (Fig. 4C–H). Both closely associated fine mineral fragments composed of iron and magnesium and larger mineral fragments rich in aluminium and silicon were observed. Aluminosilicate fragments could be the result of physical weathering of fissure walls but the source of the finely disrupted minerals is unclear.

At the bottom of the Dry Valleys, living endolithic lichens are scarce (Green *et al.*, 1999) but their previous occurrence was evidenced by the finding of mineralized remains (fossils) of lichens (Fig. 5A), which comprise recognizable mineralized structures such as algal and fungal cells.

Relationships between components of endolithic microecosystems

The relationships within the analyzed living lichen communities seemed to be extremely diverse. For instance, in Figure 5B, the growth of an epilithic thallus of *Buellia*

frigida is seen to give rise to several different endolithic microhabitats where other microorganisms thrive. Figure 5C is an enlargement of the area indicated with a square in Fig. 5B where bacteria are observed intermixed with fungal cells. Many of the microorganisms were intimately linked to their rock substratum generating complex mineral-microbe interactions, so that the lithic substratum was highly altered in the proximity of different Antarctic endolithic lichens (Fig. 2A, 5D). Figure 5D clearly shows the detachment and separation of mica minerals. Penetration by fungal hyphae was also observed in fissures in feldspar (arrows in Fig. 3B and Fig. 3C). Physical weathering by endolithic lichens was also frequently associated with a biogeochemical action, and evidence of the biomobilization of different elements and biomineralization processes could be observed around the organisms. Figure 5E shows a cavity occupied by mycobiont cells of *Lecidea cancriformis*, with a mineral deposit visible at the base of the cavity. Calcium and silicon distribution maps obtained by EDS revealed a large amount of calcium in the mineral deposits within the cavity in contrast to the silicon-rich composition of the substratum (feldspar plagioclase). Thus, these deposits could be identified as calcium oxalate biominerals. In the lithic substratum, zones with small amounts of calcium can be detected reflecting intense calcium depletion in this feldspar plagioclase in an area close to thalli of *L. cancriformis* (low-calcium zone indicated by asterisks in Fig. 5E). This biomobilization was clearly related to a biomineralization process, as indicated by the extensive calcium oxalate deposits in the cavity colonized by *L. cancriformis*.

Discussion

We have shown that endolithic lichens are components of endolithic biofilms, where close chemical, physical and biological relationships are established among symbiont cells and their immediate environment. It was not usually possible to identify clearly

differentiated thallus layers in these endolithic lichens, although a degree of organization of the algal cells and fungal hyphae was observed. Endolithic lichens colonizing Beacon sandstones occupy the airspaces of the rock and do not form an organized thallus (Friedmann 1982). The distribution patterns shown by the symbiont cells in the present study were similar in granite from the extremely dry Canada Glacier site on the floor of Taylor Valley and the more equable granites at Granite Harbour on the Ross Sea coast. This suggests that the distribution of symbiont cells in the fissures and cracks in the granite is not determined solely by the external environmental conditions, but also by factors differing on a small spatial scale such as the physico-chemical features of the rock (Matthes *et al.* 2001; De los Ríos *et al.* 2005). Different ecological niches can be attributed to the different habitats occupied by endolithic lichens: cells of chasmoendolithic lichens colonize the fissures of the substratum, cryptoendolithic forms colonize its cavities and euendolithic ones actively penetrating the rock (Golubic *et al.*, 1981). To a large extent the type of rock determines the microbial ecological niche. In the granite analyzed here, the predominant ecological niche was chasmoendolithic (Fig. 1), whereas the higher porosity of sandstone promotes the presence of cryptoendolithic forms in other lichen dominated communities of the Ross desert (Friedmann 1982).

The endolithic environment appeared to be altered by the activity of the microbial cells. In the present study several mineral-lichen interactions were observed in the form of geophysical and geochemical effects. Fungi were the biological components that produced the most intense geophysical

weathering of the rocks, and mica was the mineral most susceptible to this bioalteration; for example mica minerals become more modified than feldspar and quartz. Fungi not only participate in the alteration processes because of their physiological properties, but they also exert mechanical forces because of their ability to penetrate and spread through hard substrata (Sterflinger 2000) and due to their water binding capacity causing volume changes in wet and dry periods (De los Ríos *et al.*, 1999). The ability of epilithic lichen thalli to disaggregate the rock surface has been frequently described (Banfield *et al.* 1999; Aghamiri & Schwartzman 2002; Bjelland & Thorseth 2002; De los Ríos *et al.* 2002). However, the real extent of the weathering capacity of endolithic lichens has yet to be fully evaluated. Although fungal action is probably not the only cause of the fissure formation, the images obtained during this study suggest that fungal penetration of granite could contribute to fissure formation and certainly be involved in subsequent widening of the fissure. The colonization of fissures by fungal hyphae, as observed here, and the growth of apothecia at the surface (De los Ríos *et al.* 2005), can have dramatic biogeophysical effects on granite rocks.

The present work has found compelling evidence that endolithic lichens are involved in biogeochemical processes occurring in granite. Biogeochemical processes prevail in the early stages of lichenization (Cooks & Otto 1990) and these may be similar in the endolithic lichens examined here, in which it was not possible to distinguish well-differentiated lichen thallus layers. Calcium biomobilization related to Antarctic endolithic lichens was observed in the present

study, and potassium mobilization in biotites and feldspar has also been recently ascribed to endolithic Antarctic lichens (De los Ríos *et al.* 2005). In addition to calcium oxalate, the fine minerals composed of iron and magnesium observed here around the cells are also likely to be the consequence of biomineralization processes. The presence of Fe-rich diagenetic minerals and biogenic clays has been previously reported around chasmoendolithic hyphae and bacterial cells (Wierzbos *et al.* 2003). Biomineralization processes are related to the local chemical composition of the substratum (Bjelland *et al.* 2002; De los Ríos *et al.* 2005) and can give rise to chemical microenvironments that could affect the establishment of another microorganism in the zone (De los Ríos *et al.* 2002). These processes may have physiological consequences: biogenic minerals have been found to completely envelop symbiont cells or to occupy a large proportion of the colonized area, suggesting these deposits could act as a barrier against the exchange of nutrients and affect nutrient cycling in the biofilm. The 'fossilized' cells described in endolithic systems could be the result of these interactive processes rather than a change in the external habitat as has been suggested (Friedmann *et al.* 1994). In the present work mycobiont cells were found to be covered by EPS closely associated with mineral fragments, suggesting a certain level of interaction of these compounds with rock components and their possible involvement in the detected biogeochemical processes (Barker & Banfield 1996; Barker *et al.* 1998). The formation of extracellular microbial polymeric layers may be controlled not only by nutrient availability, but also by the availability of metal ions to which the cell is exposed (Beveridge 1989; Ferris 2000).

For the first time, we have been able to analyse the physiological state of symbiont cells *in situ*, without removing the biofilm from the lithic substratum. This allows the precise detection and localization of living and dead cells within the lithic substratum. It was found that mycobiont hyphae and photobiont cells in different physiological

states were intermixed, and that the majority of cells were viable. This confirms the results of a previous study (De los Ríos *et al.* 2004) that explored the physiological state of different endolithic microorganisms in biofilms. Such a high proportion of viable cells might indicate that these systems are very young and little dead material has yet accumulated, or that they are very old and long-lived with a very low productivity and very long-lived cells. At present we cannot answer this question. Some endolithic systems have been shown to be very old, even thousands of years (Johnston & Vestal 1991; Sun & Friedmann 1999), but dates of more samples are needed in order to make any generalizations. Few studies have assessed productivity on any time scale although it is suspected that productivity of endoliths is lower than that of epilithic lichens. The results of Friedmann *et al.* (1993), derived from cryptoendolithic communities, suggest that net ecosystem productivity from long-term events is only about $3 \text{ mg C m}^{-2} \text{ y}^{-1}$.

The biological success of these endolithic lichens requires the development of life strategies that will allow them to maintain their populations in this extreme habitat over a period of time (Block 1994). The survival of endolithic lichens in continental Antarctica might be more a question of avoiding rather than tolerating the extreme conditions outside the microhabitat (Friedmann 1982; Friedmann *et al.* 1993; De los Ríos *et al.* 2003; Cowan & Tow 2004). Production of EPS is a survival mechanism and the matrix is thought to be one of the key biofilm components involved in the protection of the component microorganisms from the environment (Davey & O'Toole 2000; De los Ríos *et al.* 2004). Extracellular polymeric substances are able to form microenvironments with conditions different from those of the bulk in terms of radiation received, capacity of water retention and pH, among other factors, which could favour the survival of lithobionts (De los Ríos *et al.* 2003). In addition, EPS can be considered long-term accumulators of carbon and

energy (Wolfaardt *et al.* 1999) and are thus of great interest in terms of adaptation to Antarctic conditions. The endolithic strategy is also closely linked to the interactions of the lichen symbiont cells with the lithic substrata (Johnston & Vestal 1993). Interactions between the components of the biofilms and their substrata determine the existence of different microhabitats and chemical microenvironments in these lithic microecosystems (Bungartz *et al.* 2004; De los Ríos *et al.* 2002, 2003). The spatially close association of endolithic symbiont cells with the lithic substratum, and the alteration of bedrock minerals and synthesis of biominerals observed in the antarctic granite analyzed in the present study, also supports this hypothesis.

Whilst lichen biogeochemical activity can limit the bioavailability of some metals, it can also release other nutrients to the microecosystem; the present study is an example of how endolithic lichens can actively contribute to mineral cycling (Wierzbosch & Ascaso 1996, 1998). It is known that lichens occupy extensive areas in the world, but this area is much greater if endolithic growth forms are also included in such global estimates. This means their global contribution to biogeochemical cycles both through mineral cycling and metabolic activity might need to be re-assessed.

The authors thank Fernando Pinto, Charo Santos and Sara Paniagua for technical assistance and Ana Burton for reviewing the English. This study was funded by grants REN2003-07366-C01/C02 and BOS2003-02418 of the *Plan Nacional I+D*.
